FILM THICKNESS MEASURING METHOD AND APPARATUS, AND THIN FILM

DEVICE MANUFACTURING METHOD AND MANUFACTURING APPARATUS USING

SAME

BACKGROUND OF THE INVENTION

The present invention relates to a method for measuring

the thickness of optically transparent thin film, and more

particularly, to a technique wherein measurement points are

automatically determined for measuring the thickness of an

optically transparent thin film on a circuit pattern which is

formed on a wafer and buried under an optically transparent

thin film. More particularly, the invention relates to a

technique used in a manufacturing line manufacturing

semiconductor devices onto silicon wafers, or the like,

whereby significant measurement points are determined based

upon the premise that they are for measuring the thickness of

an optically transparent thin film which has undergone

levelling after the film deposition stage. In addition to the

foregoing, optically transparent thin films include resist

films and insulating films, and the like, employed in

manufacturing stages of thin film devices, such as DVD, TFT,

LSI reticles, and the like.

Let us consider, for example, a CMP (Chemical Mechanical

Polishing) process in a manufacturing line for semiconductor

devices. A semiconductor device is manufactured by forming

devices or wiring patterns onto a silicon wafer, by processes

1

such as film deposition, exposure, etching, and the like. In recent years, in order to achieve higher precision and higher density in such devices, there have been moves towards greater fineness and increased layering, which have resulted in an increase in the number of indentations in the wafer surface. Such indentations in the wafer impede the light exposure process, which is essential in forming wiring, and the like, and therefore levelling of the wafer surface is carried out. The aforementioned CMP process is used for this levelling process, wherein the surface of the wafer is levelled by polishing based on chemical and physical actions. CMP is a commonly known technique in the related technological field.

However, there are many cases in, for example, a wiring stage in the manufacturing process for a semiconductor device, where the surface is not completely levelled, even after CMP processing. The reason for this is non-uniformity of the local occupancy ratio of the circuit pattern (pattern surface ratio) located in the lower layer of the transparent film. It is generally known that there is a correlation between the surface area ratio of the circuit pattern located in lower layer of the transparent film and the thickness of the optically transparent thin film after processing. A large variation in the film thickness after processing this will cause problems in the subsequent exposure and etching stages, and hence the film thickness must be controlled after CMP processing.

2

Controlling film thickness in CMP is considerably problematic. In the prior art, this has generally been achieved by means of processing time. In other words, a polishing rate is calculated from the polishing amount as derived by measuring the film thickness before and after CMP processing, and the polishing time for which CMP was actually performed, and this calculated polishing rate is supplied as feed-back into the next processing time. Furthermore, a method may also be employed whereby the film thickness is controlled by measuring at predetermined measurement points, in order to confirm that the film thickness after processing comes within a prescribed film thickness range, this film thickness measurement being performed on a pattern formed in the peripheral region of the chip, or the like, (dummy pattern) having sufficient size to be measured satisfactorily by a conventional measuring device. However, in this film thickness controlling method, the film thickness is not measured in the required position in the middle of the actual device pattern (the actual fine circuit pattern of the product).

Japanese Patent Laid-open No. (Hei)6-252113 and Japanese Patent Laid-open No. (Hei)9-7985 disclose in-situ measuring systems capable of measuring the film thickness at the device pattern. Furthermore, Japanese Patent Laid-open No. (Hei)9-109023 discloses an in-line measuring system for achieving increased through-put by measuring film thickness after processing whilst the device is held in water and before it

3

has been cleaned. In Japanese Patent Laid-open No. (Hei)6-252113 described above, the spectrum of the interference pattern produced by the film from white light is analyzed with respect to frequency, and the absolute value of the thin film is calculated by observing the relationship between the frequency component relating to the spectral waveform and the film thickness. Moreover, in Japanese Patent Laid-open No. (Hei)9-7985 described above, the change with respect to processing time of the intensity of the interference pattern produced by the film from a laser (single-wavelength source) is detected and the film thickness is calculated from the frequency component relating to that waveform.

Moreover, Japanese Patent Laid-open No. (Hei)9-193995 discloses an in-situ measuring system for detecting a processing end point by detecting the extreme position (wavelength) of the spectral waveform.

Furthermore, Japanese Patent Laid-open No. 2000-241126 discloses a method for calculating a thin film thickness by fitting a detected spectral waveform and a theoretical waveform derived from a model.

Furthermore, Japanese Patent Laid-open No. 2000-9437 proposed previously by the present applicants discloses a technique whereby the film thickness of a transparent thin film on a circuit pattern buried by an optically transparent thin film can be measured, provided that the pattern area ratio within the measurement field of view of the film

4

thickness measuring device (pattern area of circuit pattern occupying the measurement field of view) is equal to or greater than a certain value. In the technique described in Japanese Patent Laid-open No. 2000-9437, it is possible to achieve precise measurement of the thickness of a transparent thin film on the actual circuit pattern of the product, and by evaluating the thickness distribution within the chip, it is possible to perform accurate evaluation of the film thickness, without requiring expertise.

However, the respective patents disclosed above do not disclose a technique for automatically setting measurement points for film thickness measurement to significant points. Desirably, the measurement points for measuring film thickness should satisfy the following conditions : (1) enable film thickness evaluation within wafer surface and within whole chip (for example, evaluation of maximum film thickness and minimum film thickness), and (2) number of measurement points should be few (to maintain throughput), but in order to determine measurement points satisfying these conditions, the operator is required to have expertise, and a long period of time is necessary for the actual point determining operation.

Moreover, Japanese Patent Laid-open No. (Hei)8-304023 discloses a technique whereby, in order to confirm the position at which measurement is actually made when measuring film thickness, measurement point candidate co-ordinates on the wafer under observation are calculated from relative

5

positional data for the wafer and representative measurement point co-ordinate values, as derived from design information, by moving the XY table in such a manner that representative measurement points in a captured image coincide with predetermined target measurement points. Moreover, Japanese Patent Laid-open No. (Hei)6-331320 discloses a technique whereby, in order to confirm the position at which measurement is actually made when measuring film thickness, the optical reflectivity in a prescribed region is studied, and the film thickness is measured at a position of highest reflectivity, this being a region where the portion below the transparent film on the face irradiated by the light beam is formed entirely by an electrode.

The techniques disclosed in Japanese Patent Laid-open No. (Hei)8-304023 and Japanese Patent Laid-open No. (Hei)6-331320 are aimed principally at accurately locating the position of the XY table on which the wafer is mounted, with respect to the film thickness measuring device, rather than automatically determining the required measurement points located in the actual body of the chip product. In other words, in measuring film thickness after CMP processing, it is essential to measure the thickness of the transparent film on the circuit pattern buried below an optically transparent thin film, and if the technique disclosed in Japanese Patent Laid-open No. 2000-9437 described above is used to perform this film thickness measurement, then it is necessary to specify

locations on the transparent thin film where the circuit pattern exceeds a prescribed pattern area ratio. However, the operator's task of determining a plurality of measurement points on the chip, by visually observing a microscope field of view or a screen displaying a captured image, is laborious and time-consuming, and the measurement points thus determined are not based on objective judgement criteria.

Considering, for example, a wiring process in a semiconductor device manufacturing process, a completely flat surface often does not result, even when CMP processing is applied. The reason for this is that the ratio of the local plane of the layer beneath the film that is occupied by the wiring pattern (the pattern area ratio) is not uniform. It is generally known that there is a correlation between the surface area ratio of the pattern located in the lower layer and the thickness of the film after processing.

If there is a large variation in the film thickness after processing, this will cause defects in the subsequent exposure and etching steps, and hence the film thickness must be controlled after processing.

Japanese Patent Application Laid-open No. 2000-9437 discloses a technique which permits submicron-order measurement of the film thickness on a device pattern, in order to evaluate the variation in the film thickness. The film thickness is determined by frequency analysis of detected spectral data. However, in this method, if the film thickness

to be measured is small compared to the detection wavelength band, then it becomes difficult to measure the film thickness. Nevertheless, Japanese Patent Laid-open No. 2000-241126 discloses a method for measuring film thickness by fitting, which is applicable to films of relatively small film thickness also. However, in the technology thus disclosed, in cases where the thickness of a thin film formed on a finely detailed pattern is being measured, the measurement accuracy is affected greatly by the pattern density, and hence the method cannot be used for high-precision measurement with respect to a variety of patterns.

Therefore, it is an object of the present invention to provide a film thickness measuring method and apparatus based on fitting, whereby film thickness can be measured even with respect to finely detailed patterns, and a thin film device manufacturing method and manufacturing apparatus using same.

Moreover, Japanese Patent Application Laid-open No. 2000-9437 discloses a method wherein accurate evaluation of film thickness can be achieved without great proficiency, by evaluating the film thickness distribution within a chip.

However, in order to evaluate the film thickness distribution in the chip, for example, to measure 10 × 100 points, it has been necessary for the operator to set the positions of the 100 measurement points.

Therefore, it is a further object of the present invention to provide a method and apparatus for automatically

10 =

determining measurement points, and to provide a method and apparatus for manufacturing a thin film device using same.

SUMMARY OF THE INVENTION

The present invention was devised with the foregoing in view, and in the method according to the present invention, firstly, measurement points are determined for performing film thickness measurement in order to measure the thickness of an optically transparent film formed so as to cover a circuit pattern formed on a substrate, the film thickness is then determined by successively measuring at the measurement points thus determined, and the distribution of the film thickness on the substrate, or on chips formed severally on the substrate is derived.

In other words, in the present invention, light is irradiated onto a particular chip of a plurality of chips on a wafer formed with a plurality of chips whereon a circuit pattern and an optically transparent thin film for covering said circuit pattern are formed respectively; the light reflected by the particular chip region of said wafer due to said irradiated light is detected; measurement points for measuring the film thickness of said optically transparent thin film on said wafer are determined by using information for the spectral waveform data of the reflected light thus detected; and the film thickness of said optically transparent thin film at said measurement points is measured, by

9

successively irradiating light onto the measurement points thus determined.

Furthermore, in the present invention, light is irradiated onto a portion of a wafer whereon a circuit pattern and an optically transparent thin film for covering said circuit pattern are formed respectively; the light reflected by said portion of said wafer due to said irradiated light is detected; regions where the thickness of said optically transparent thin film on said wafer can be measured are determined, by using information for the spectral waveform data of the reflected light thus detected; and the film thickness of said optically transparent thin film in said regions where the film thickness can be measured is measured, by irradiating light onto the regions where the film thickness can be measured thus determined.

Moreover, in the present invention, light is irradiated onto a particular chip of a plurality of chips on a wafer formed with a plurality of chips whereon a circuit pattern and an optically transparent thin film for covering said circuit pattern are formed respectively; the light reflected by the particular chip region of said wafer due to said irradiated light is detected; a plurality of measurement points or regions for measuring the film thickness of said optically transparent thin film on said wafer are determined by using information for the spectral waveform data of the reflected light thus detected; the film thickness of said optically

10

transparent thin film at said plurality of measurement points

or regions is measured, by successively irradiating light onto

the plurality of measurement points or regions thus

determined; and the distribution of the film thickness of said

optically transparent thin film from the information for the

film thickness of the optically transparent thin film thus

measured.

In order to achieve the object of film thickness

measurement by fitting, in the present invention, a new model

is hypothesized. That is, in cases where the dimension of the

pattern formed on the sample being measured is equal to or

smaller than the wavelength of the light used for measurement,

a boundary region which accounts for the pattern edge region

(pattern step region) is established, and the effects of this

boundary region in fitting are taken into consideration.

Moreover, in order to achieve the object relating to

selection of film thickness measurement points, measurement

points having prescribed conditions are determined

automatically on the basis of the design information, the

measurement point periphery image, and the spectral waveform

detected at the measurement points.

Furthermore, the processing conditions of the respective

processing apparatuses in the semiconductor device

manufacturing line are controlled on the basis of the film

thickness information measured to a high degree of accuracy by

the aforementioned fitting method.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

The embodiment of the present invention relates to an
example where the present invention is applied with respect to
CMP in a manufacturing process for a semiconductor device and
is used to control film thickness after processing of a film
formed on a wafer surface.

Firstly, the method of measuring film thickness by
fitting will be described.

Fitting has been used conventionally for measuring film
thickness. Supposing a film comprising a plurality of layers
and having a uniform structure in the measurement field of
view, as illustrated in Fig. 35, then provided that the film
thickness and the material (refractive index and absorption
coefficient) of each layer is already known, the surface
reflectivity R_j of layer j is expressed by the logic equation

18

shown in Formula 1. In other words, the surface reflectivity R_N of the film can be determined by progressive application of Formula 1, starting from the bottom layer.

[Formula 1]

$$Rj = \frac{r_{j+1} + R_{j-1}e^{-2\pi i 2dj\frac{n_j}{\lambda}}}{1 + r_{j+1}R_{j-1}e^{-2\pi 2dj\frac{n_j}{\lambda}}}$$

where

$$r_{j+1} = \frac{n_{j+1} - n_j}{n_{j+1} + n_j}.R_0 = r_1$$

R_j : surface reflectivity of jth layer

r_j : interface reflectivity of jth layer

n_j : refractive index of jth layer (complex refractive index)

d_j : film thickness of jth layer

Therefore, a logical refractive index is calculated, taking the film thickness of the measurement object as an unknown value, and the film thickness can then be derived by resolving this unknown value in such a manner that the error between the logical refractive index and the actually detected refractive index is a minimum. In some cases, the material of the film may also be set as an unknown value, in addition to the film thickness.

However, since it is hypothesized that the layer structure within the measurement field of view is uniform, this method cannot be applied to cases where the layer

19

structure within the measurement field of view is not uniform.

In order to be able to measure film thickness in cases where

the layer structure within the measurement field of view is

not uniform, it is necessary to hypothesize models in the form

of logic equations wherein a plurality of layer structures are

combined.

Here, it is supposed that two layer structures as shown

in Fig. 37 are combined. Fig. 37 is a schematic diagram of the

cross-section of the film to be measured.

The logic equation differs according to the optical

detection system and the complexity of the measurement pattern.

Firstly, a condensing optical system as illustrated in Fig. 38

will be considered. The light from the light source 103 is

formed into parallel light by the lens system 105 and

irradiated onto the sample 101. The reflected light from the

sample 101 is condensed by the lens system 105. A spatial

filter 106 is provided at this position and transmits only the

0th order light component of the reflected light. The spatial

filter 106 has the effect of eliminating light scattered at

the surface of the sample, and light diffracted by the pattern.

The light passed by the spatial filter 106 is formed again

into parallel light by the lens system 107, and is then

focused by the lens system 109 and split by a beam splitter

110, whereby spectral data can be obtained. In this case, by

inserting a field of view aperture 108 between the lens system

107 and the lens system 109, it is possible to set a detection region of a desired size.

In the case of this optical system, only the forward reflected light from the measurement field of view is focussed at one point, and hence the model equation is that shown in Formula 2.

[Formula 2]

$$|R|^2 = |a_1 R_1 + a_2 R_2|$$

where

a_1 : surface area ratio of first layer structure in measurement field of view

a_2 : surface area ratio of second layer structure in measurement field of view

R_1 : surface area reflectivity of first layer structure alone

R_2 : surface area reflectivity of second layer structure alone

Next, an image forming system such as that illustrated in Fig. 39 is considered as the optical system. The light emitted from the light source 203 is irradiated onto the sample 201 via an object lens 220. The light reflected from the sample 201 is focussed again via the lens system 211 - 213. By inserting a field of view aperture 208 at this focusing position, it is possible to set a detection region of a desired size.

The light is split by a beam splitter 210 and spectral data thereof is obtained. In this case, a spatial filter 206 is provided on the Fourier transformation face of the lens system 211 - 213, and by only transmitting 0th order light, it eliminates the effects of scattered light from the surface of the sample, and light diffracted by the pattern, as above.

The model equation in the case of this optical system differs according to the size of the pattern being measured and the repetition width.

If the size of the pattern being measured and the repetition width are both sufficiently large in comparison to the detection wavelength, for example, if a repeated pattern 115 having a size of several μm as illustrated in Fig. 40 is measured in a measurement field of view of φ 10 μm diameter, using a detection wavelength band of 400 - 800 nm, then the model equation will be as shown in Formula 3.

[Formula 3]

$$|R|^2 = a_1|R_1|^2 + a_2|R_2|^2$$

When measuring a pattern of the order of several μm or above, as illustrated in Fig. 40, it is possible to consider the respective layer structures as independent structures (Fig. 41). In other words, in this case, it can be considered that there will be no interference between the reflected light from different points on the same plane, and hence the model equation, Formula 3, applies weightings to the surface

22

reflectivity value for each respective independent layer

structure, according to the ratio occupied by the

corresponding layer in the measurement field of view (pattern

area density values, a_1, a_2), and then adds together these

reflectivity values.

On the other hand, in cases where the size of the pattern

to be measured, or the repetition width, is equal to or less

than the detection wavelength, for example, if measuring a

repetition pattern 118 of size 1   μm or less as illustrated in

Fig. 4 in a measurement field of view of φ   10 μm di ameter,

using a detection waveband of 400 – 800 nm, then in contrast

to the case illustrated in Fig. 40, the respective layer

structures   cannot   be   considered   each   as   independent   structures.

In the case illustrated in Fig. 42, it is necessary to   ,

consider an intermediate model equation between the two models

shown in Fig. 37 and Fig. 41. In other words, it is necessary

to consider the boundary structure where the two structures

are combined, in addition to the respective independent layer

structures. It is hypothesized that, in this boundary

structure, there is mutual interference between the reflected

light from different spatial positions. The model equation for

the totality of the reflected light can be derived by adding

weightings to the respective structures (including the

boundary structure) according to the surface area ratio of

each in the measurement field of view, and then finding the

sum thereof, as in the model equation shown in Formula 4.

[Formula 4]

$$|R|^2 = a_1|R_1|^2 + a_2|R_2|^2 + a_{12}|R_{12}|^2$$

where

$$|R_{12}|^2 = |b_1 R_1 + b_2 R_2|^2$$

R_{12} : surface area reflectivity of boundary layer

structure

b_1 : surface area ratio of first layer structure in

boundary structure

b_2 : surface area ratio of second layer structure in

boundary structure

By adopting the equation above as the model equation for

fitting, according to the circumstances, it is possible to

determine the prescribed film thickness.

In addition to the film thickness, it is also possible to

set, as the parameter for fitting, the material of the film,

or the surface area ratio of the respective layer structures

in the measurement field of view.

Desirably, the surface area ratio of each layer structure

is set in advance. However, situations where error arises in

the calculation results can be imagined if there is a

difference between the set surface area ratio and the actual

surface area ratio, due to misalignment of the measurement

field of view, or the like. Therefore, if the surface area

ratio is to be derived as a parameter of the fitting method, then it does not need to be set in advance, and furthermore, the occurrence of error due to positional misalignment, or the like, can be prevented.

If the film material is set as the parameter, then an approximation equation such as the Cauchy equation shown in Formula 5 which incorporates information relating to the material (refractive index, absorption coefficient, and the like) should be used.

[Formula 5]

$$n = n_0 / \lambda^0 + n_1 / \lambda^2 + n_2 / \lambda^4 + n_3 / \lambda^6 + n_4 / \lambda^8$$

$$n = k_0 / \lambda^0 + k_1 / \lambda^2 + k_2 / \lambda^4 + k_3 / \lambda^6 + k_4 / \lambda^8$$

where

λ : wavelength

n : refractive index

$n_0 - n_4$: coefficient (refractive index)

k : absorption coefficient

$k_0 - k_4$: coefficient (absorption coefficient)

Generally, the method used to determine a parameter by fitting is the 'method of least squares'. If the model equation is complex, as in Formula 2 to Formula 4, then in many cases, a non-linear method, such as the Rabenberg Macquart method, or the like, is adopted.

Furthermore, even in cases where the number of combined layer structures is three or more, the present equations can

25

still be used to determine the film thickness of a particular film. If Formula 2, Formula 3 and Formula 4 are expanded and standardized in the case of three or more layer structures, then the resulting equations are as shown respectively in

[0043]

[Formula 6]

$$|R|^2 = \left|\sum a_m R_m\right|^2$$

where

m : number of structures

a_m : surface area ratio of mth layer structure in measurement field of view

R_m : surface reflectivity for mth layer structure alone

[Formula 7]

$$|R|^2 = \sum a_m |R_m|^2$$

[Formula 8]

$$|R|^2 = \sum a_m |R_m|^2 + \sum a_{pq} |R_{pq}|^2 + \sum a_{uvw} |R_{uvw}|^2 + ...$$

where

$$|R_{pq}|^2 = |b_p R_p + b_q R_q|^2$$

$$|R_{uvw}|^2 = |b_u R_u + b_v R_v + b_w R_w|^2$$

a_{pq} : surface area ratio of boundary structure between pth and pth layer structures in measurement field of view

R_{pq} : surface reflectivity of boundary structure between pth and qth layer structures

a_{uvw} : surface area ratio of boundary structure of three structures, the uth, vth and wth layer structures, in the measurement field of view;

R_{uvw} : surface reflectivity of boundary structure of three structures, the uth, vth and wth layer structures

b_p : surface area ratio of pth layer structure in boundary structure between pth and qth layer structures;

b_q : surface area ratio of qth layer structure in boundary structure between pth and qth layer structures;

b_u : surface area ratio of uth layer structure in boundary structure between three structures, the uth, vth and wth layer structures;

b_v : surface area ratio of vth layer structure in boundary structure between three structures, the uth, vth and wth layer structures;

b_w : surface area ratio of wth layer structure in boundary structure between three structures, the uth, vth and wth layer structures;

Desirably, the number of parameters to be fitted is small, as they affect the calculation time and the calculation error. However, in the case of three structures or more, and particularly, in the case of Formula 8, the number of parameters is very high. The overall number of parameters can be reduced by ignoring factors which have little influence, such as structures occupying a very small surface area ratio in the measurement field of view, or, if one film thickness is

27

to be derived as a function containing another film thickness as a variable, by introducing the aforementioned function instead of the film thickness as a fitting parameter.

Fig. 46 shows a comparison between a case where the boundary structure is considered, and a case where it is not considered, when detecting light from the measurement object illustrated in Fig. 37 by means of light of the same waveband. As Fig. 46 reveals, by taking the boundary structure into consideration, the error between the detected value and the logic value is reduced.

Although it also depends on the structure of the measurement object if the boundary structure is taken into consideration, it is possible to obtain a measurement accuracy of 10 nm or less for an object of the order of 100 nm, or if the conditions are adjusted, a measurement accuracy of approximately 1 - 4 nm. If the boundary structure is not taken into consideration, then for the reasons stated above, the measurement accuracy declines and the error rises from the approximately 10 - 20 nm to several 10 nm, and in the worst cases, fitting to the detected value becomes impossible and measurement cannot be performed.

As the measurement object becomes smaller with respect to the detection waveband, the ratio of the measurement field of view occupied by the boundary region increases. Therefore, when measuring film thickness in finely detailed patterns of 1 μm or less using   an imaging optical system, it is imperative

28

that the boundary structure is taken into consideration in the fitting calculation.

Next, a method is described for determining measurement points for measuring film thickness of a transparent thin film on a circuit pattern buried under an optically transparent thin film, with respect to a wafer which has undergone a CMP stage in a semiconductor device manufacturing process.

In Japanese Patent Laid-open No. 2000-9437 described above, it is disclosed that the film thickness distribution in a chip can be determined by utilizing the fact that the film thickness can be measured in any part of the pattern, provided that the pattern area ratio within the measurement field of view is equal to or above a certain value. By using this method, even an operator of little expertise is able to evaluate the film thickness distribution within the chip or wafer, accurately, (for detailed description of the film thickness measurement method, and the like, see Japanese Patent Laid-open No. 2000-9437.) However, in the technique in Japanese Patent Laid-open No. 2000-9437, if, for example, a chip is being measured at a total of 10 × 10 = 100 points, then it has been necessary for an operator to determine each respective measurement point.

In one embodiment of the present invention, the light is irradiated onto a wafer surface, the light reflected from the wafer is detected, and measurement points for measuring the film thickness are determined on the basis of the spectral

waveform data of the reflected light thus reflected. Details
of this method are described below.

In automatically determining measurement points for
measuring the film thickness of a transparent film on a
circuit pattern buried under an optically transparent thin
film, it is necessary to judge whether or not a measurement
point is over the prescribed pattern and has a pattern area
ratio that is sufficient for performing measurement. This
judgement is made by analyzing the spectral waveform detected
in the proposed measurement region.

Spectral waveforms detected in regions where measurement
is possible have respectively different characteristics from
those detected in regions where measurement is not possible.
For example, Fig. 1 and Fig. 2 respectively show typical
examples of spectral waveforms detected in a measurable region
and a non-measurable region, in the case of a sample which has
undergone a CMP stage in an LSI wiring process. Fig. 1 shows
spectral waveform 1 for reflected light from a measurable
region, and Fig. 2 shows spectral waveform 2 for reflected
light from a region that is troublesome to measure.

The characteristic of the waveform in Fig. 1 is a
waveform comprising a superimposed low frequency component and
high frequency component. On the other hand, the
characteristic of the waveform in Fig. 2 is that the high
frequency component in Fig. 1 is dominant and the low
frequency component is scarcely discernable. This disparity is

30

due to the difference between a case where the interference component produced by the reflected light from the pattern is dominant, and a case where the interference component produced by the reflected light from the lower layer is dominant.

This difference in waveform characteristics can be taken as a difference in frequency components. Therefore, by frequency analysis of the waveform, the characteristics can be extracted and it can be judged whether or not measurement is possible. Item 3 in Fig. 3 and item 4 in Fig. 4 indicate the results of frequency analysis relating to Fig. 1 and Fig. 2, respectively. As a method for determining whether or not measurement is possible from these results, it is possible, for example, to calculate the ratio between the intensity 5 of the high frequency component and the intensity 6 of the low frequency component in Fig. 3, compare this ratio with a predetermined threshold value, and designate the region to be measurable if the ratio exceeds the threshold value, and designate it to be non-measurable if the ratio does not exceed the threshold value.

Moreover, as shown in Fig. 4, it is also possible to conceive a method whereby the intensity of the high frequency component is compared with a predetermined threshold value 7 and the region is designated as measurable if the intensity exceeds this threshold value, and non-measurable if it does not. Frequency analysis methods, such as FFT (Fast Fourier Transform), MEM (Maximum Entropy Method), and the like, may be

used for analysing the light frequency.

Furthermore, instead of frequency analysis, it is also possible to adopt a judgement method based on extracting the periodicity of the waveform, by calculating the self-correlation function thereof.

A method such as that illustrated in Fig. 5 and Fig. 6, which does not relate to waveform periodicity, might also be adopted. In this method, for example, the maximum values 8, 9 of the waveform are extracted, and judgement is made by comparing the magnitude of the variation in these maxima with a predetermined threshold value. More specifically, since the spectral waveform for a region where film thickness measurement is possible has a large low frequency component, then the variation in maxima will be large in the case of a measurable region, and conversely, this variation will be small in the case of a non-measurable region.

Furthermore, if the structure to be measured is already known, then a method can be adopted which judges measurement points by means of fitting with respect to a logical waveform. For example, this judgement can be made by fitting a logical spectral waveform calculated from the structure situated over the pattern only onto the detected spectral waveform. Moreover, it is also possible to conceive of a method wherein previous values for the film thickness of the structure to be measured are known and a range including these values is set, waveform fitting is performed within this range, and the region is

32

designated as measurable if the fitting error (for example,

the square-sum of the error between the two waveforms) is

equal to or less than a certain threshold value, and otherwise,

it is designated as non-measurable. Fig. 7 and Fig. 8 show

examples of cases where wavelength fitting has been performed.

In Fig. 7, the error with respect to the fitted waveform 10 is

relatively small, whereas in Fig. 8, this error is large.

Fig. 32 principally shows the composition of an optical

measurement system of a measuring device for performing

judgement by detecting and analysing spectral waveforms. This

measuring device is also used as a film thickness measuring

device. In practice, the film thickness measuring device also

comprises an XY stage, a stage drive system, input operating

section, and a control section for controlling the whole

device, and the like, but these components are omitted from

the illustration in Fig. 32.

In Fig. 32, numeral 50 denotes a wafer, 51 is a white

light source consisting of a halogen lamp, or the like, 52 is

a pin hole, 53 is a beam splitter, 54 is a lens, 55 is an

aperture, 56 is a diffraction lattice, 57 is a detector, 58 is

a processing circuit, and 59 is a display device.

White light emitted from the white light source 51 passes

through the pin hole 52 and beam splitter 53, is converted to

parallel light rays by the lens 54 and then passes through the

aperture 55, where it is irradiated onto the film to be

measured on the surface of the wafer 50. The light reflected

by the wafer 50 passes through the aperture 55 and lens 54,

the light path thereof is then changed by the beam splitter 53,

and it is irradiated onto the diffraction lattice 56. The

light split by the diffraction lattice 56 is focused on the

detector 57, whereby the spectral waveform thereof can be

derived. The processing circuit 58 executes judgement

processing by means of a judgement algorithm such as the

foregoing, and the judgement results and spectral waveform

data can be viewed on the display device 59, as and when

necessary. The judgement results are stored in storing means

(not illustrated) in correspondence with co-ordinate values

from a reference position on the chip, as derived by referring

to the movement position of the XY stage on which the wafer 50

is mounted.

Next, a method for automatically investigating and

determining measurement points on the basis of the

aforementioned judgement method will be described. For example,

as illustrated in Fig. 18, in the case of measuring the film

thickness at 10 × 10 = 100 points on one chip, the respective

provisional reference measurement points 12 that are

previously set are not necessarily measurable points.

Therefore, if a provisional reference measurement point 12 is

in fact a non-measurable point, then it is necessary to set a

measurable point located adjacently to the provisional

reference measurement point 12, as a measurement point. In Fig.

18, numeral 21 indicates an image of one chip.

Fig. 9 - Fig. 14 are diagrams showing examples of a procedure for investigating measurement points. Fig. 9 and Fig. 10 illustrate cases where the spectral waveform is detected successively at respective points, and measurability is judged, by setting the number of investigate points and the interval between investigate points in the horizontal direction X and vertical direction Y.

Fig. 9 illustrates a case where a total of 15 points, namely, 5 points in the X direction spaced at interval dX and 3 points in the Y direction spaced at interval dY, are investigated, wherein, firstly, a reference measurement point 12 is investigated (the spectral waveform thereof is detected and judged), whereupon the investigation is continued in successive fashion starting from points adjacent to the reference measurement point 12.

In the case of Fig. 10, a total of 25 points are investigated, five each in the X and Y directions, at respective intervals of dX and dY, a provisional reference measurement point 12 being investigated (by detecting and judging the spectral waveform thereof) first, whereupon the respective points are investigated successively in square spiral fashion from the provisional reference measurement point 12.

In the respective cases of Fig. 9 and Fig. 10, it is also possible to set the first point judged to be measurable as a result of the investigation, as the measurement point for

35

measuring the film thickness, halting any investigation of subsequent points, or alternatively, it is also possible firstly to detect and judge the spectra of all of the investigation points, and then to set the most suitable point from the judgement results, or the nearest measurable point to the provisional reference measurement point 12 (or provisional reference measurement point 12 itself if it is a measurable point), or the point which best satisfies both conditions, as the measurement point for performing film thickness measurement. This applies similarly to the cases of Fig. 11 to Fig. 14 below.

Furthermore, if the spectral detection and judgement processes can be performed at high-speed, then it is also possible, as shown in Fig. 11, to perform spectral detection and judgement in real time by performing continuous investigation following a square spiral path such as that Fig. 10, instead of performing intermittent investigation as described in Fig. 9 and Fig. 10.

Fig. 12 - Fig. 14 illustrate cases where the processing performed in a square spiral fashion in Fig. 10 and Fig. 11 is conducted in a circular spiral fashion. Fig. 12 illustrates an example where respective points previously determined at intervals of $d\theta$ on a path of travel are investigated in an intermittent fashion, and Fig. 13 illustrates an example where respective points previously determined at intervals of a movement distance d1 on a path of travel are investigated in

36

an intermittent fashion. Moreover, Fig. 14 illustrates a case where investigation is performed in continuous fashion along the same path of travel as Fig. 12 and Fig. 13, light detection and judgement being carried out in real time.

The investigation of the prescribed region in the vicinity of the provisional reference measurement point 12, taking this provisional reference point 12 as an origin, may be conducted in various ways other than the examples described above, for example, it may also be conducted in the fashion of similarly-shaped concentric quadrilaterals, or in concentric circular fashion.

The aforementioned processing for automatically investigating (performing spectral detection and judgement) and determining measurement points is conducted at all the provisional reference measurement points 12 and the respective vicinities thereof, and as shown in Fig. 19, a total of 10 × 10 = 100 measurement points 13 are determined on one chip. The co-ordinate values for each measurement point 13 thus determined are stored in storing means (not illustrated), in the form of positional co-ordinates from a reference point (reference position mark) 27 (see Fig. 20) on that chip, for example.

Here, since each chip on the single wafer comprises the same thin film device, the operation of automatically setting measurement points 13 may be conducted for each chip, or it may be conducted for a plurality of chips which are to be

37

subjected to film thickness measurement, or, depending on

circumstances, it may be conducted one for all the chips.

Furthermore, for wafers comprising the same product, it is

possible to carry out the process of automatically determining

measurement points for the first wafer (first wafer chip) only ,

and to apply the respective measurement point co-ordinates

determined from the first wafer to the subsequent wafers, but

according to requirements, it is also possible to implement a

process of automatically redefining the measurement points for

the wafers, at a suitably selected timing.

Fig. 15 – Fig. 17 show schematic illustrations of a

display screen of an investigation region, in a case where the

process of automatically defining measurement points as

described above was actually implemented by the measuring

device (film thickness measuring device) shown in Fig. 32. In

Figs. 15 to 17, examples are shown according to the

investigation sequence shown in the preceding Fig. 10.

In Fig. 15 – Fig. 17, 15 is an investigation screen

display window; and 16A – 16G are investigation points (unit

investigation regions for performing spectral detection and

judgement). Moreover, the horizontal black bar markings

represent a circuit pattern 18 buried in an optically

transparent thin film forming an uppermost layer, and the

vertical grey bar markings indicate a circuit pattern 19

buried in a lower transparent film being the thin film that is

to be subjected to film thickness measurement.

Fig. 15 illustrates a case where investigation points 16A

corresponding to provisional reference measurement points 12

are investigated, and in this case, since the purpose is to

measure the thickness of the transparent film on the circuit

pattern 18 indicated by the black horizontal bars, the

judgement result at the first investigation point 16A will

show a zero pattern surface ratio of circuit pattern 18, and

hence this point will be judged to be invalid for film

thickness measurement, as a result of the spectral waveform

analysis and judgement; (without providing a detailed

explanation here, the spectral waveform containing the light

component reflected by the aforementioned circuit pattern 19

in the lower layer differs greatly from the spectral waveform

in the case of the circuit pattern 18, and therefore it can

readily be extracted and disregarded by the processing and

judging means.)

Fig. 16 illustrates a situation where the next

investigation point 16B is being investigated. The judgement

result at this investigation point 16B, similarly to the

judgement result for the investigation point 16A, is that film

thickness measurement is not possible. In the diagrams, the

"× symbol within a circle indicates investigation points for

which a judgement result of 'measurement not possible' is

returned.

Fig. 17 shows a situation where, investigation points 16C

- 16F have been investigated and similarly judged to be

invalid for measurement, and investigation point 16G is now

being investigated. In the situation in Fig. 17, the pattern

surface ratio at investigation point 16G is equal to or

greater than a prescribed value, and therefore it is judged

from the spectral waveform analysis and judgement process,

that film thickness measurement is possible at this point.

Thereafter, if all the investigation points are to be

investigated, then a similar process is conducted for each of

the remaining investigation points.

By respectively performing the investigation described

above in the vicinity of each of the provisional reference

measurement points 12 at the 100 points in the image 21 of the

whole chip in Fig. 18, a total of 100 measurement points 13

which are guaranteed to a pattern area ratio of the prescribed

value   or   above   are   determined   on   the   chip,   as   shown   in   Fig.   19.

Fig. 20 is a schematic illustration of an example of an

operating screen, in a case where the aforementioned

measurement points are determined automatically, and this

diagram depicts a situation where the image for one chip

extracted by a suitable enlarging and imaging device is

displayed on a suitable display device. An operator (worker)

refers to the display screen shown in Fig. 20 and, by using a

cursor 26, or the like, causes a reference point 27 of the

chip, for example, to be recognized and stored in the control

section of the measuring device shown in Fig. 32, whereupon,

taking this reference point 27 as an origin, the operator sets

and stores, for example, 10 × 10 provisional reference measurement points 12, by inputting co-ordinate values via a keyboard, or by operating the cursor, or the like. Thereupon, measurement points 13 for measuring the film thickness are automatically determined at 10 × 10 point by executing the series of steps described above. Consequently, the provisional reference measurement points 12 may be set readily in a rough fashion, such as equidistantly, and hence the burden on the operator is extremely light. Fig. 21 is an example of a window screen for confirming the provisional reference measurement points 12 once set.

Moreover, it is also possible for an operator to determine the points manually, rather than determining them automatically. In this case, for example, a desired point is selected by the cursor 26, or the like, as shown in Fig. 20, an expanded image of that section is displayed (see Fig. 21), and in this state, the operator controls the XY stage, or the like, to determine the measurement points. This is similar to the prior art, but in order to judge whether or not film thickness measurement is possible, the spectral waveform analysis and judgement processing according to the present embodiment described above is performed at any position, and a suitable measurement points can be determined by taking this as reference information for setting measurement points.

Next, a further embodiment of the present invention is

described. This embodiment automatically determines

measurement points for film thickness measurement by suitably

processing image data captured in the vicinity of a

predetermined provisional reference measurement point. Fig. 22

to Fig. 29 shows one example of a processing sequence for

performing judgement processing on the basis of the image of

the vicinity of a provisional reference measurement point

captured as an enlarged image. The provisional reference

measurement points are set in a similar manner to the

foregoing embodiment.

Fig. 22 gives a schematic illustration of an image of the

vicinity of a provisional reference measurement point. In Fig.

22, the circuit pattern 18 indicated by the black horizontal

bars is a pattern buried under an uppermost optically

transparent thin film, and the object here is to measure the

thickness of the transparent film on this circuit pattern 18.

Furthermore, the small circle 33 indicates a measurement field

regions for measuring the film thickness, which is centred on

the provision reference measurement point. In the case of Fig.

22, the measurement field region 33 is not positioned over the

circuit pattern, and therefore it is judged that film

thickness cannot be measured.

Therefore, edge detection processing is performed with

respect to the image in Fig. 22, as illustrated in Fig. 23,

whereupon horizontal line extraction processing is performed,

as illustrated in Fig. 24. Furthermore, in order to

investigate the distribution of the horizontal lines thus

extracted, the image region in Fig. 24 is divided up as

illustrated in Fig. 25, whereupon the distribution of

horizontal lines within each division is converted to a

numerical(quantized), as illustrated in Fig. 26, and then

weightings for the local density distribution of the

horizontal lines are applied, using a suitable statistical

calculation method, or the like, as illustrated in Fig. 27,

whereby the most suitable regions 36 are determined, wherein

it is sufficiently guaranteed that the pattern area ratio of

the circuit pattern 18 will exceed a prescribed value.

Fig. 28 shows an image wherein the candidate regions 36

determined as illustrated in Fig. 27 are combined with the

screen showing the circuit pattern 18 in Fig. 22. In this

state, by determining the amount of movement detected when the

XY stage is moved to control the regions 36 so that they enter

within the measurement field region 33, or the amount of

movement required in the position of the measurement field

region 33 in Fig. 28 (Fig. 22) until the measurement field

region 33 overlaps with fields 36, it is possible

automatically to define the measurement points where film

thickness measurement is possible, from the amounts of

movement thus determined, and the central co-ordinates of the

measurement field region centred on the provisional reference

measurement point in Fig. 22 (co-ordinates of the provisional

reference measurement point). Fig. 29 illustrates the

relationship between the circuit pattern and the measurement field region 34 centred on an automatically determined measurement point.

A further embodiment of the present invention is now described. This embodiment automatically determines measurement points for measuring film thickness by data processing, such as suitable image processing, of the previously determined design data for the vicinity of a provisional reference measurement point. The provisional reference measurement point is set in a similar manner to the foregoing embodiments, by incorporating design data, such as the CAD data for a chip, and displaying this data on a screen.

In this embodiment, instead of the captured image data, the CAD data for the circuit pattern buried under the uppermost optically transparent thin film is obtained, after which the measurement points where film thickness measurement can be performed are determined automatically by similar processing to that illustrated in Fig. 22 to Fig. 29.

According to the three embodiments described above, it is possible to determine a plurality of measurement points on a chip for measuring film thickness, swiftly and accurately, on the basis of clear, general judgement criteria, without being dependent on the experience or expertise of the operator. Therefore, it is possible to assess the thin film distribution within the chip surface, or the wafer surface, accurately, regardless of the expertise of the operator.

Next, a method for accurately managing film thickness by means of a small number of measurement points is described. Firstly, the film thickness is measured respectively at the measurement points determined by the method described above. In this case, the film thickness measurement method is the same as the method used to determine the measurement points described above. The measurement results can be conveyed to the operator by displaying the measured film thickness distribution in the chip surface or the measured film thickness distribution in the wafer surface, on a monitor screen.

The film thickness can be controlled by evaluating the film thickness distribution of each of the measurement points thus obtained. In this case, to manage the film thickness accurately using a small number of measurement points, it is most efficient to measure two points, namely, the maximum and minimum point of the film thickness. In Fig. 30, numeral 37 is an illustration where the film thickness distribution in one chip is indicated by contour lines, based on the measurement results for 10 × 10 = 100 points, for example, and the sections indicated by max and min denote the regions of maximum and mini mum film thickne ss. Therefore, as shown in Fig. 31, these max and min points should be selected as the minimum number of measurement points 41 for controlling the film thickness in the chip. Furthermore, if more accurate evaluation is required, then as indicated by the enlarged

diagrams 38, 39 in Fig. 30, it is possible to achieve more precise control by assessing the film thickness in the respective max and min regions at fine intervals, in order to determine the position of the maximum and minimum film thickness. It is also possible to use evaluation points outside the maximum and minimum regions of film thickness, in order to control the film thickness using a small number of measurement points.

Fig. 33 is a diagram showing a manufacturing line for thin film devices to which the measuring device in Fig. 32, in other words, a film thickness measuring device, is applied. In the example depicted here, this device functions both as a device for determining measurement points for performing film thickness measurement and as a film thickness measuring device.

In Fig. 33, 60 is a film deposition device, 61 is a CMP processing system comprising a CMP device 62, washing device 63 and film thickness measuring device 64, 65 is an exposure device, and 66 is an etching device.

A wafer (not illustrated) is repeatedly subjected to film deposition, CMP processing, exposure, etching, and the like, whereby the respective chips are fabricated thereon as thin film devices. After the first wafer for a certain product has been film deposited by the film deposition device 60, levelled by the CMP device 62 and washed by the washing device 63, it is transferred to the film thick ness measuring device 64. Here, the operator observes an image of the chip displayed on the

46

display of the film thickness measuring device 64, and sets

provisional reference measurement points as described above,

whereupon he or she instructs the film thickness measuring

device 64 to implement a process for automatically determining

the measurement points for performing film thickness

measurement. Receiving this instruction, the film thickness

measuring device 64 executes processing for automatically

determining the measurement points, as described above, in

accordance with a previously defined measurement point

determining algorithm. The data for each measurement point

thus obtained is stored in a measurement condition storing

section 64a, along with other measurement conditions.

Thereupon, the film thickness measuring device 64 measures the

film thickness at each measurement point, using the data for

each measurement point stored in the measurement conditions

storing section 64a, by means of a similar method to that

disclosed in Japanese Patent Laid-open No. 2000-9437 described

above, and it determines the film thickness distribution. Next,

the wafer undergoes suitable processing for fabricating thin

film devices, by means of the exposure device 65, etching

device 66, and the like.

When the next wafer of the same product is transferred to

the film thickness measuring device 64, the film thickness

measuring device 64 immediately measures the film thickness at

the respective measurement points using the data for the

measurement points stored in the measurement conditions

storing section 64a, and it then conducts processing for determining the film thickness distribution. In this case, for subsequent wafers of the same product, it is possible to implement measurement using a minimum number of measurement points, as illustrated in Fig. 30 and Fig. 31, on the basis of the data obtained for the film thickness distribution analysis for the first wafer.

Moreover, the film thickness data and film thickness distribution data for each measurement point as obtained by the film thickness measuring device 64 is transferred to a control device (not illustrated), which evaluates and controls the processing by referring to this data.

In the example in Fig. 33 described above, the device functions both as a device for determining measurement points for performing film thickness measurement, and as a film thickness measuring device, but these device may be provided separately. Fig. 34 shows one such example.

In Fig. 34, a plurality of CMP processing systems 61 perform processing in parallel, each CMP processing system 61 being provided with a film thickness measuring device 64. 64' is a stand-alone type film thickness measuring device provided once only for a plurality of CMP processing systems 61, and this stand-alone film thickness measuring device 64' functions as a device for executing processing for determining measurement points for film thickness measurement, the data for the respective measurement points thus obtained being

48

supplied to the respective film thickness measuring devices 64
of each CMP processing system 61.

Needless to say, the function of the stand-alone film
thickness measuring device 64' may also be combined in the
film thickness measuring device 64 of one of the CMP
processing systems 61. Moreover, the film thickness measuring
devices do not necessarily have to be incorporated into the
CMP processing system.

As described above, according to the present invention,
it is possible automatically to determine measurement points
for measuring the film thickness of transparent film on a
circuit pattern buried under an optically transparent thin
film, swiftly and accurately, on the basis of general,
reliable judgement criteria, without depending on the
experience or expertise of the operator. Therefore, it is
possible accurately to assess the film thickness distribution
in a chip surface or wafer surface, by adopting a measurement
point determining method of this kind, thereby contributing to
improved yield rate and throughput.

Next, as shown in Fig. 47, in a manufacturing line for
semiconductor devices, it is possible to control the
processing conditions of the processing equipment which
processes the semiconductor substrate, for example, the film
forming apparatus, CMP apparatus, exposure apparatus, etching
apparatus, and the like, by using the measurement results for

film thickness obtained by the method for measuring film thickness according to the present invention.

In other words, in a manufacturing process for a semiconductor device comprising: a film forming step for forming a thin film onto a substrate; a CMP step for processing the thin film formed on the substrate; an exposure step for coating resist onto the processed thin film and exposing a pattern thereon; and an etching step for etching the CMP processed thin film using the exposed resist as a mask; film thickness measurement according to the present invention is performed with respect to a substrate which has undergone the film forming step or a substrate which has undergone the CMP step, whereby the thickness of the optical transparent thin film on the substrate is measured to an accuracy of 10 nm or less, and the process conditions of at least one of the film forming step, CMP step, exposure step or etching step, can be controlled according to the results of this measurement.

If, as a result of measuring the film thickness, it is found that the film thickness varies, then this can be considered to have an effect on both the exposure step and the etching step. In the case of the exposure step, the focus is set on any region within the shot, and then exposure is performed, so defects will occur is there is significant variation in film thickness. In this case, if the surface undulations caused by film thickness variation within the shot

50

come within the focal depth of the exposure, at the least,

then the focal point can be set to an optimum height by

evaluating the variation of the film thickness within the shot,

and hence the incidence of defects can be reduced.

In the case of etching also, if there is significant

variation in the film thickness, then it may be considered

that hole penetration faults, and the like, may occur. In this

case also, by evaluating the variation of the film thickness

and optimising the etching time, and the like, it is possible

to reduce the incidence of defects.

As regards the film-forming step also, if, for example,

variation in the film thickness after polishing is altered

from variation before polishing, then by evaluating the

variation in film thickness after polishing, thickness at film

forming may be optimized.

By reflecting the measurement results in the conditions

of various processes, as well as the CMP process, of course,

it is possible to reduce the incidence of defects.

According to the present invention, it is possible to

determine measurement points for controlling film thickness

which permit accurate evaluation, automatically and in a short

period of time, without requiring great proficiency. Moreover,

by applying the aforementioned method, yield and throughput

can be improved. For example, it is possible to perform high-

precision film thickness control in a CMP step of a method and

manufacturing line for manufacturing semiconductor devices

51

onto silicon wafers, as described above, and hence the throughput of the step can be improved.

The invention may be embodied in other specific forms without departing from the spirit or essential characteristics thereof. The present embodiment is therefore to be considered in all respects as illustrative and not restrictive, the scope of the invention being indicated by the appended claims rather than by the foregoing description and all changes which come within the meaning and range of equivalency of the claims are therefore intended to be embraced therein.
